### **Grammars & Parser Combinators**

Haskell and Cryptocurrencies

Dr. Andres Löh, Well-Typed LLP

Dr. Lars Brünjes, IOHK

Dr. Polina Vinogradova, IOHK

2019-01-30

### Goals

- Grammars
- Parse trees
- Parser combinators
- The Alternative class

### Credits

This lecture is based on Johan Jeuring's lecture on "Languages and Compilers", Utrecht University, 2016-2017.

All errors are of course our own.

## **Grammars**

## Alphabets & languages

### Alphabet

An alphabet is a finite set of symbols (for example the set of all UTF8-characters, corresponding to the type **Char** in Haskell).

### Alphabets & languages

### **Alphabet**

An alphabet is a finite set of symbols (for example the set of all UTF8-characters, corresponding to the type **Char** in Haskell).

### Language

A language over an alphabet is a subset of all words/sentences over the alphabet (sequences of symbols from the alphabet).

## Example: palindromes

The language PAL of palindromes over the alphabet  $\{a, b, c\}$  is defined as follows ( $\epsilon$  denotes the empty word):

- $\epsilon$  is in PAL,
- a, b and c are in PAL,
- If P is in PAL, then aPa, bPb and cPc are also in PAL.

#### Grammars

#### Grammars

A grammar is a formalism to describe a language inductively. Grammars consist of rewrite rules, called productions.

# A grammar for palindromes

- $P \rightarrow \epsilon$
- $P \rightarrow a$
- $P \rightarrow b$
- $P \rightarrow c$
- $P \rightarrow aPa$
- $P \rightarrow bPb$
- $P \rightarrow CPC$

- The language PAL is defined as follows:
  - $\epsilon$  is in PAL,
  - · a, b and c are in PAL,
  - If P is in PAL, then aPa, bPb and cPc are also in PAL.

## A grammar for palindromes

- $P \rightarrow \epsilon$
- $P \rightarrow a$
- $P \rightarrow b$
- $P \rightarrow c$
- $P \rightarrow aPa$
- $P \rightarrow bPb$
- $P \rightarrow cPc$

- A grammar consists of multiple productions.
   Productions can be seen as rewrite rules. If the left hand side matches, it can be replaced by the right hand side.
- The grammar uses auxiliary symbols called nonterminals – that are not in the alphabet and hence can't appear in the final word.
- The symbols from the alphabet are also called terminals.

## A grammar for palindromes

Starting from a nonterminal, we can apply productions successively until we reach a word of terminals:

$$P \rightarrow \epsilon$$

$$P \rightarrow a$$

$$P \rightarrow b$$

$$P \rightarrow b$$

$$P \rightarrow c$$

$$P \rightarrow aPa$$

$$P \rightarrow bPb$$

$$P \rightarrow aPa$$

$$P \rightarrow bPb$$

 $P \rightarrow cPc$ 

We call such a sequence a derivation. All words that can be derived from a nonterminal are in the language generated by the nonterminal. The nonterminal is called the start symbol of the language.

## Context-free grammars

The grammars we consider are restricted:

 The left hand side of a production always consists of a single nonterminal.

Grammars with this restriction are called context-free.

## Remarks about grammars

- · Not all languages can be generated by a grammar.
- Even fewer languages can be generated by a context-free grammar.
- Languages that can be generated by a context-free grammar are called context-free languages.
- Context-free languages are relatively easy to deal with algorithmically, and therefore most programming languages have a context-free syntax.
- · Multiple grammars may generate the same language.

# Language of single digits

Dig	$\rightarrow$	0
Dig	$\rightarrow$	1
Dig	$\rightarrow$	2
Dig	$\rightarrow$	3
Dig	$\rightarrow$	4

$$\begin{array}{c} \textit{Dig} \rightarrow 5 \\ \textit{Dig} \rightarrow 6 \\ \textit{Dig} \rightarrow 7 \\ \textit{Dig} \rightarrow 8 \\ \textit{Dig} \rightarrow 9 \end{array}$$

# Language of single digits

$Dig \rightarrow 5$
Dig $ ightarrow$ 6
Dig $ ightarrow$ 7
Dig $ ightarrow$ 8
Dig $ ightarrow$ 9

Multiple productions for the same nonterminal can be joined:

$$Dig \rightarrow 0 \mid 1 \mid 2 \mid 3 \mid 4 \mid 5 \mid 6 \mid 7 \mid 8 \mid 9$$

$${\it Digs}\,\rightarrow\,\epsilon\,\mid\,{\it Dig}\,{\it Digs}$$

$$\mathrm{Digs} \, o \, \epsilon \mid \mathrm{Dig} \, \mathrm{Digs}$$

This grammar allows sequences with leading zeroes:

$$Digs \Rightarrow Dig \ Digs \Rightarrow Dig \ Digs \Rightarrow Dig \ Dig \ Digs$$
  
 $\Rightarrow Dig \ Dig \ Dig \ \epsilon \Rightarrow \ldots \Rightarrow 007$ 

$$\mathrm{Digs} 
ightarrow \epsilon \mid \mathrm{Dig} \ \mathrm{Digs}$$

This grammar allows sequences with leading zeroes:

Digs 
$$\Rightarrow$$
 Dig Digs  $\Rightarrow$  Dig Dig Digs  $\Rightarrow$  Dig Dig Digs  $\Rightarrow$  Dig Dig Dig  $\epsilon \Rightarrow \ldots \Rightarrow 007$ 

We allow the following star notation on the right hand side of a production to abbreviate zero or more occurences of a symbol:

$$Digs \rightarrow Dig^*$$

$$\mathrm{Digs} 
ightarrow \epsilon \mid \mathrm{Dig} \ \mathrm{Digs}$$

This grammar allows sequences with leading zeroes:

Digs ⇒ Dig Digs ⇒ Dig Dig Digs ⇒ Dig Dig Digs ⇒ Dig Dig Dig 
$$\epsilon$$
 ⇒ . . . ⇒ 007

We allow the following star notation on the right hand side of a production to abbreviate zero or more occurences of a symbol:

$$Digs \rightarrow Dig^*$$

To disallow leading zeroes, we define non-zero digits:

$$Dig_{nz} \rightarrow 1 \mid 2 \mid 3 \mid 4 \mid 5 \mid 6 \mid 7 \mid 8 \mid 9$$
  
 $Nat \rightarrow 0 \mid Dig_{nz} \ Dig^*$ 

## Integers

$$Sign \rightarrow + \mid -$$

$$Int \rightarrow Sign Nat \mid Nat$$

### Integers

$$Sign \rightarrow + \mid -$$

$$Int \rightarrow Sign Nat \mid Nat$$

The sign is optional.

### Integers

$$Sign \rightarrow + \mid Int \rightarrow Sign Nat \mid Nat$$

The sign is optional.

There is an abbreviation for optional symbols as well:

Int  $\rightarrow$  Sign? Nat

# Parse Trees

#### Parse trees

Consider the grammar  $S \to a \mid SS$ . The word aaa has (at least) the following derivations:

$$S \Rightarrow SS \Rightarrow aS \Rightarrow aSS \Rightarrow aaS \Rightarrow aaa$$
 (1)

$$S \Rightarrow SS \Rightarrow Sa \Rightarrow SSa \Rightarrow aSa \Rightarrow aaa$$
 (2)

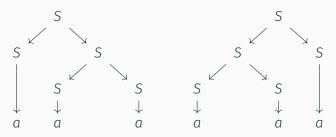

#### Parse trees

Consider the grammar  $S \to a \mid SS$ . The word aaa has (at least) the following derivations:

$$S \Rightarrow SS \Rightarrow aS \Rightarrow aSS \Rightarrow aaS \Rightarrow aaa$$
 (1)

$$S \Rightarrow SS \Rightarrow Sa \Rightarrow SSa \Rightarrow aSa \Rightarrow aaa$$
 (2)

We can visualize derivations as parse trees:

## **Ambiguity**

- A grammar where every word in the generated language has a unique parse tree is called unambiguous.
- If this is not the case, the grammar is called ambiguous.
- The grammar  $S \rightarrow a \mid SS$  is thus ambiguous.
- The semantics (i. e. "meaning") of a language will normally be defined via parse trees. Hence ambiguous grammars can have ambiguous semantics!
- Furthermore, ambiguity can also be bad for the *efficiency* of parsing.

## Parsing problem

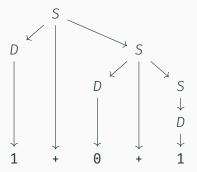

- Given a grammar G with generated language L(G) and a word S, the parsing problem is to decide whether  $S \in L(G)$ .
- Furthermore, if  $s \in L(G)$ , we want evidence (a proof, an explanation) why this is the case, usually in the form of a parse tree.

### Parse trees in Haskell

Consider this grammar:

$$S \rightarrow D+S \mid D$$
$$D \rightarrow 0 \mid 1$$

The word 1+0+1 has the parse tree

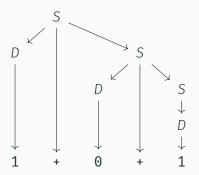

### Parse trees in Haskell

Consider this grammar:

$$S \rightarrow D+S \mid D$$
$$D \rightarrow 0 \mid 1$$

The word 1+0+1 has the parse tree

How do we best represent such a tree in Haskell?

### Parse trees in Haskell (contd.)

#### Idea

Let us represent nonterminals as datatypes:

- In any node of the parse tree, we have a choice between the productions of the nonterminal in question.
- If we want to build a value of a Haskell datatype, we have a choice between any of that datatype's constructors.

## Parse trees in Haskell (contd.)

```
data S = Plus D S | Digit D
  deriving Show
data D = Zero | One
  deriving Show
```

- We create constructors (with somewhat meaningful names) for each production.
- Nonterminals on the right hand side of a production turn into constructor arguments.
- Terminals on the right hand side of a production can be dropped – we can reconstruct them.

## Concrete and abstract syntax

Both the grammar and the Haskell datatype describe the language.

#### concrete syntax

$$S \, \rightarrow \, D + S \, \mid \, D$$

$$D \rightarrow 0 \mid 1$$

### abstract syntax

## Concrete and abstract syntax

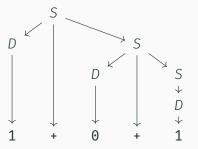

Both the grammar and the Haskell datatype describe the language.

### concrete syntax

$$S \rightarrow D+S \mid D$$
$$D \rightarrow 0 \mid 1$$

#### abstract syntax

The word 1+0+1 corresponds to the parse tree

```
Plus
One
(Plus
Zero
(Digit One))
```

#### Semantic functions

#### concrete syntax

$$S \rightarrow D+S \mid D$$

$$D \rightarrow 0 \mid 1$$

### abstract syntax

Starting from the abstract syntax, we can give *meaning/semantics* to a language, possibly in different ways.

### Semantic functions

#### concrete syntax

#### abstract syntax

$$S \rightarrow D+S \mid D$$
$$D \rightarrow 0 \mid 1$$

```
data S = Plus D S | Digit D
data D = Zero | One
```

### String representation:

```
printS :: S -> String
printS (Plus d s) = printD d ++ "+" ++ printS s
printS (Digit d) = printD d

printD :: D -> String
printD Zero = "0"
printD One = "1"
```

```
GHCi> printS (Plus One (Plus Zero (Digit One)))
"1+0+1"
```

### Semantic functions

#### concrete syntax

#### abstract syntax

$$S \rightarrow D+S \mid D$$
$$D \rightarrow 0 \mid 1$$

```
data S = Plus D S | Digit D
data D = Zero | One
```

#### Evaluation:

```
evalS :: S -> Int
evalS (Plus d s) = evalD d + evalS s
evalS (Digit d) = evalD d
evalD :: D -> Int
evalD Zero = 0
evalD One = 1
```

```
GHCi> evalS (Plus One (Plus Zero (Digit One)))
2
```

# Parser Combinators

Parser generators

Parser combinators

Parser generators external program

Parser combinators library

Parser generators external program bottom-up algorithm Parser combinators library top-down algorithm

Parser generators

bottom-up algorithm
complex theory
limited look-ahead
(usually one token)

### Parser combinators

library top-down algorithm simple underlying theory unlimited look-ahead (in principle)

### Parser generators

external program
bottom-up algorithm
complex theory
limited look-ahead
(usually one token)
only built-in abstractions

### Parser combinators

library
top-down algorithm
simple underlying theory
unlimited look-ahead
(in principle)
user-definable abstractions

### Parser generators

external program
bottom-up algorithm
complex theory
limited look-ahead
(usually one token)
only built-in abstractions
very fast generated parsers

### Parser combinators

library
top-down algorithm
simple underlying theory
unlimited look-ahead
(in principle)
user-definable abstractions
fast (for most constructs)

### Parser generators

external program
bottom-up algorithm
complex theory
limited look-ahead
(usually one token)
only built-in abstractions
very fast generated parsers

### Parser combinators

library
top-down algorithm
simple underlying theory
unlimited look-ahead
(in principle)
user-definable abstractions
fast (for most constructs)

Both approaches place certain (but different) constraints on the grammars.

### **Aside: Combinators**

- The term combinator denotes a self-contained function in lambda calculus, the formal system that Haskell and other functional programming languages are based upon.
- Parser combinators are thus a set of (small) library functions that can be used to construct parsers.

# Lexing and parsing

Often, parsing is split into two phases:

### Lexing

In a first phase, whitespace and comments are removed, and the input is organized into a list of tokens – small entities that belong together like keywords, identifiers or operators.

### **Parsing**

In the second phase, an abstract syntax tree is constructed from the list of tokens rather than from the original list of characters.

# Lexing and parsing (contd.)

In the world of generators, lexing and parsing are often performed by different generators. For example:

	Haskell	С
Lexer	alex	flex
Parser	happy	yacc / bison

# Lexing and parsing (contd.)

In the world of generators, lexing and parsing are often performed by different generators. For example:

	Haskell	С
Lexer	alex	flex
Parser	happy	yacc / bison

With parser combinators, there are different options:

- · Use only one phase,
- use the same parser combinators for both phases,
- use dedicated lexer combinators for lexing,
- · use a hand-writen special-purpose lexer,
- · combine a lexer-generator with parser combinators.

# Choosing the right parser type

What Haskell type should a parser have?

# First attempt: predicate on strings

```
type Parser = String -> Bool
```

We can write simple parsers with this type:

```
digit :: Parser
digit [c] = c `elem` "0123456789"
digit otherwise = False
```

```
eof :: Parser
eof = null
```

# First attempt: predicate on strings

```
type Parser = String -> Bool
```

We can write simple parsers with this type:

```
digit :: Parser
digit [c] = c `elem` "0123456789"
digit otherwise = False
```

```
eof :: Parser
eof = null
```

### Problem

We can't combine parsers of this type! How would we for example use digit to write a parser for two digits?

```
type Parser = String -> Maybe String
```

```
type Parser = String -> Maybe String
```

Now we can sequence parsers:

```
combine :: Parser -> Parser -> Parser
combine p1 p2 s = do
   s' <- p1 s
   p2 s'</pre>
```

```
GHCi> digit "Athens"
Nothing
GHCi> digit "123"
Just "23"
GHCi> (digit `combine` digit) "123"
Just "3"
```

```
type Parser = String -> Maybe String
```

Let's define a parser for letters, too:

```
type Parser = String -> Maybe String
```

Or better, let's abstract the common pattern:

```
digit = satisfy (`elem`"0123456789")
```

```
letter = satisfy
  (`elem` ['a' .. 'z'] ++ ['A' .. 'Z'])
```

```
type Parser = String -> Maybe String
```

Using satisfy, we can define a parser for a specific character:

```
char :: Char -> Parser
char c = satisfy (== c)
```

```
GHCi> char 'x' "xyz"

Just "yz"
```

```
type Parser = String -> Maybe String
```

We can even define the \*-combinator, called many in Haskell:

```
many :: Parser -> Parser
many p s = case p s of
  Nothing -> Just s
  Just s' -> many p s'
```

```
GHCi> many letter "123"

Just "123"

GHCi> many letter "abc123"

Just "123"
```

type Parser = String -> Maybe String

GHCi> (many letter `combine` char 'a') "xyzab"
Nothing

### Problem

But what about the grammar  $S \to letter^*$  a? With this type for parsers, we only ever get at most one result, but we need to consider *all* possible results to handle cases like these.

```
type Parser = String -> [String]
```

```
eof :: Parser
eof [] = [[]]
eof (_:_) = []
```

We define digit, letter and char as before in terms of satisfy.

```
type Parser = String -> [String]
```

```
combine :: Parser -> Parser -> Parser
combine p q s = do
   s' <- p s
   q s'</pre>
```

(Same code, but now in the list-monad!)

```
many :: Parser -> Parser
many p s = s : combine p (many p) s
```

```
GHCi> many letter "abc123" ["abc123", "bc123", "c123", "123"]
```

```
type Parser = String -> [String]
```

This solves our problem with the previous attempt:

```
GHCi> (many letter `combine` char 'a') "xyzab"
["b"]
```

```
type Parser = String -> [String]
```

With this definition for parsers, we can choose between parsers:

```
choose :: Parser -> Parser -> Parser choose p q s = p s ++ q s
```

```
GHCi> (letter `choose` digit) "abc"
["bc"]
GHCi> (letter `choose` digit) "123"
["23"]
```

### Problem

There is still one big problem with our definition: We only know whether a given word belongs to the language or not, but we don't get a parse tree or other result.

Let's fix that!

```
newtype Parser a = Parser
{runParser :: String -> [(a, String)]}
```

We want to make **Parser** an instance of several typeclasses, hence we wrap it in a **newtype**.

```
newtype Parser a = Parser
{runParser :: String -> [(a, String)]}
```

```
digit, letter :: Parser Char
digit = satisfy (`elem`"0123456789")
letter = satisfy
  (`elem` ['a' .. 'z'] ++ ['A' .. 'Z'])
```

```
eof :: Parser ()
eof = Parser $ \ s -> case s of
[] -> [((), [])]
(_:_) -> []
```

```
newtype Parser a = Parser
{runParser :: String -> [(a, String)]}
```

What about char? We could define.

```
char c = satisfy (== c)
```

But then char would produce a parser of type

Parser Char, where it seems more natural to give the result the type

Parser () instead.

We need to be able to change the result type!

char :: Char -> Parser ()

char c = const () <\$> satisfy (== c)

```
newtype Parser a = Parser
{runParser :: String -> [(a, String)]}

Let's make Parser an instance of Functor!

instance Functor Parser where

fmap :: (a -> b) -> Parser a -> Parser b

fmap f p = Parser $ \ s ->

[(f a, s') | (a, s') <- runParser p s]</pre>
```

```
newtype Parser a = Parser
{runParser :: String -> [(a, String)]}
```

What about sequencing? - What type should

```
Parser a `combine` Parser b
```

have?

```
Parser (a, b)?
```

That's awkward! - Let's instead make Parser an instance of Applicative!

```
newtype Parser a = Parser
{runParser :: String -> [(a, String)]}
```

```
instance Applicative Parser where
  pure :: a -> Parser a
  pure a = Parser $\s -> [(a, s)]
 (<*>) :: Parser (a -> b) -> Parser a -> Parser b
 p < *> q = Parser $ \setminus s -> do
   (f, s') <- runParser p s
   (a, s'') <- runParser q s'
   return (f a, s'')
```

```
newtype Parser a = Parser
{runParser :: String -> [(a, String)]}
```

The **Functor** and **Applicative** instances immediately give us other useful combinators:

```
(<$) :: a -> Parser b -> Parser a
(<*) :: Parser a -> Parser b -> Parser a
(*>) :: Parser a -> Parser b -> Parser b
```

These are useful when we don't care about some of the intermediate results:

```
char :: Char -> Parser ()
char c = () <$ satisfy (== c)</pre>
```

```
newtype Parser a = Parser
{runParser :: String -> [(a, String)]}
```

What about choice? – There is a suitable typeclass for this in **Control.Applicative**, too, that we haven't seen yet:

```
class Applicative f => Alternative f where
  empty :: f a
  (<|>) :: f a -> f a -> f a
```

```
newtype Parser a = Parser
{runParser :: String -> [(a, String)]}
```

With **Alternative**, we get some useful combinators from the base libraries for free:

```
many, some :: Alternative f => f a -> f [a]
```

(many means "zero or more occurences", the \*-operator, some means "one or more occurences".)

Furthermore, we get

```
optional :: Alternative f => f a -> f (Maybe a)
```

for optional values.

```
newtype Parser a = Parser
{runParser :: String -> [(a, String)]}
```

# instance Alternative Parser where empty :: Parser a empty = Parser \$ const [] (<|>) :: Parser a -> Parser a -> Parser a p <|> q = Parser \$ \ s -> runParser p s ++ runParser q s

### Example parser

$$S \rightarrow D+S \mid D$$
$$D \rightarrow 0 \mid 1$$

```
data S = Plus D S | Digit D
data D = Zero | One
```

```
parseD :: Parser D
parseD = Zero <$ char '0'
    <|> One <$ char '1'</pre>
```

### Example parser

```
S \rightarrow D+S \mid DD \rightarrow \mathbf{0} \mid \mathbf{1}
```

```
data S = Plus D S | Digit D
data D = Zero | One
```

```
GHCi> runParser parseS "1+0+1"
[ (Plus One (Plus Zero (Digit One)), "")
, (Plus One (Digit Zero), "+1")
, (Digit One, "+0+1")]
```

```
GHCi> runParser (parseS <* eof) "1+0+1"
[(Plus One (Plus Zero (Digit One)), "")]</pre>
```

### Fifth and final attempt: Other token types

In order to handle other tokens besides characters, we can do one more generalization:

```
newtype Parser t a = Parser
{runParser :: [t] -> [(a, [t])]}
```

### Fifth and final attempt: Other token types

In order to handle other tokens besides characters, we can do one more generalization:

```
newtype Parser t a = Parser
{runParser :: [t] -> [(a, [t])]}
```

```
eof :: Parser t ()
eof = Parser $ \ ts -> case ts of
[]     -> [((), [])]
  (_ : _) -> []
```

The Functor, Applicative and Alternative instances can easily be generalized to this setting.

### Fifth and final attempt: Other token types

In order to handle other tokens besides characters, we can do one more generalization:

```
newtype Parser t a = Parser
{runParser :: [t] -> [(a, [t])]}
```

And we can generalize **char** to an analoguous function **token** that works on all tokens types (which can be compared for equality):

```
token :: Eq t => t -> Parser t ()
token t = () <$ satisfy (== t)</pre>
```
